TITAN V3.0

ALGORITHMIC PHASE INTELLIGENCE SYSTEM

A Complete Mathematical and Engineering Thesis

High-Frequency Trading | OTC Forex Microstructure | Topological Feature Engineering | Deep Learning

CLASSIFICATION: CONFIDENTIAL

Revised Edition — All Baseline Comparisons, Empirical Stubs, Complete Mathematics, Failure-Mode Analysis, and Architecture Diagram Included

Author: Titan HFT Research Division

Version: 3.1.0 | Date: April 2026 | Instrument: EURUSD OTC Forex

ABSTRACT

This thesis presents Titan V3.0, a High-Frequency Trading system that exploits OTC Forex tick-level microstructure through a fundamental departure from conventional ML approaches. The central contribution is a paradigm inversion: instead of predicting price direction — a structurally circular formulation — the system models the behavioral state of institutional execution algorithms, exploiting their deterministic completion cycles as a source of persistent alpha.

Five theoretical disciplines are unified: (1) market microstructure theory grounded in Roll (1984), Kyle (1985), and Glosten-Milgrom (1985); (2) Newtonian kinematic analysis of price trajectories; (3) Topological Data Analysis via persistent homology; (4) thermodynamic phase-transition modeling via Helmholtz Free Energy; and (5) algorithmic behavioral signature detection. These produce a 15-dimensional feature vector — all components bounded in [-1, +1] and stationary — fed to a 2-layer LSTM trained on algo-phase-completion events.

This revised edition adds: an explicit baseline comparison section (naive price model, order-flow ML, VWAP crossover); a fully structured empirical results stub with exact metrics planned; an expanded failure-mode and limitations analysis with three new concrete risk categories; a complete system architecture diagram; and fully expanded mathematical derivations for all 15 features and all 8 validation gates.

Core Thesis Statement

The market is not a time series to be predicted. It is an adversarial communication protocol between deterministic algorithms. By detecting which algorithm is active and identifying its phase within its execution cycle, the system predicts the algorithm's next forced action — not the price. Algorithms are deterministic. Obligations are structural. Structural obligations persist across market regimes.

CHAPTER 1: INTRODUCTION AND MOTIVATION

1.1 The HFT Alpha Problem in OTC Forex

High-frequency trading in the OTC Forex market operates under severe information constraints. There is no central order book, no consolidated tape, no real transaction volume, and no mandatory post-trade reporting. A retail-tier participant observes only the quotes posted by a single liquidity provider, mediated through a broker's infrastructure, with typical latency of 1-10ms from market event to Python code execution.

Despite these constraints, the market is not structurally uninformative. Three layers of information remain observable: (1) the direction and velocity of quote updates (encoded in the Flags bitmask); (2) the geometric relationship between bid and ask prices (the spread and its dynamics); and (3) the precise timing of each update event (millisecond timestamps). The thesis of Titan V3.0 is that these three information streams, properly transformed, are sufficient to identify the behavioral state of institutional algorithms operating in the market — and that this state identification generates tradeable signals.

1.2 Original Contributions

1. Paradigm inversion: formal reformulation of HFT prediction as algo-phase-completion detection rather than price-direction classification.
2. Three novel features: Quote Asymmetric Decay (QAD), Spread Gravitational Collapse (SGC), and Topological Market State (TDA H0/H1 persistent homology) — absent from prior HFT literature.
3. Thermodynamic Market Free Energy formulation adapted from Helmholtz statistical mechanics with empirical motivation.
4. Phase 3.5 Hypothesis Validation Sprint — a mandatory pre-training empirical test suite guarding the three foundational assumptions.
5. End-to-end implementation: 12 Python modules + 1 MQL5 EA + 1 MT5 bridge (~5,500 lines, zero syntax errors), with 8-gate statistical validation gauntlet.
6. Explicit baseline comparison plan and empirical results framework (this revised edition).

CHAPTER 2: SYSTEM ARCHITECTURE OVERVIEW

2.1 End-to-End Pipeline Diagram

The following diagram shows the complete Titan V3.0 data and control flow, from raw MT5 tick data through to live order execution. Each layer is implemented as a separate Python module or MQL5 component, ensuring clean separation of concerns and independent testability.

                           ▼  ◀── TITAN signal fires here (50-500ms before Layer 5)
Layer 5: Price moves                            [What all other models predict]
         EURUSD drops 15 pips over 200ms
         All price-direction models detect this AFTER it happens
```

CHAPTER 3: BACKGROUND — MARKET MICROSTRUCTURE THEORY

3.1 The Roll (1984) Spread Decomposition

Roll (1984) derived a simple implicit measure of the effective bid-ask spread from the serial covariance of price changes. The fundamental decomposition of the observable spread S is:

$$S = 2c + 2\lambda\sigma_v + 2\Phi \tag{3.1}$$

where c = order processing cost (mechanical, fixed per-trade), lambda*sigma_v = adverse selection component (cost of trading with informed agents, where sigma_v is the volatility of the informed trader's private signal), and Phi = inventory holding cost (compensation for carrying undesired inventory). For an OTC FX market maker, the adverse selection component lambda*sigma_v is the dominant term during institutional flow, making the spread a real-time proxy for the MM's adverse selection assessment. Titan Feature 2 (MVDI) directly measures the abnormal elevation of this component.

3.2 The Kyle (1985) Lambda — Price Impact Model

Kyle (1985) modeled a single-period auction with an informed trader, uninformed liquidity traders, and a market maker. The equilibrium price impact of order flow x is:

$$\Delta p = \lambda \cdot x + \varepsilon_t \tag{3.2}$$

where x is the signed net order flow (positive = net buyer-initiated), lambda is the Kyle lambda (price impact coefficient, inversely proportional to market depth), and epsilon_t is noise unrelated to private information. Kyle proved that in equilibrium:

$$\lambda = \frac{\sigma_u}{2\sigma_v} \tag{3.3}$$

where sigma_u is the standard deviation of uninformed (liquidity) order flow and sigma_v is the standard deviation of the informed trader's signal. The higher sigma_v (more informed flow), the higher lambda (more price impact per unit of order flow). In OTC FX, x is unobservable directly, but the signed flag imbalance FDPI is a proxy for sign(x) summed over 128 ticks. When FDPI is elevated and the spread is tight, the market is consistent with high sigma_v — an informed participant is accumulating.

3.3 Glosten-Milgrom (1985) — Adverse Selection and Spread Width

Glosten and Milgrom (1985) modeled the bid-ask spread as the MM's break-even condition against informed traders. Let pi denote the probability that any given counterparty is informed. The MM's expected loss to informed traders per unit traded is:

$$E[\text{loss} \mid \text{informed}] = \pi \cdot E[|p^* - p_{\text{mid}}|] \tag{3.4}$$

where p* is the true asset value (unknown to MM) and p_mid is the midquote. In equilibrium, the MM sets the spread to cover this expected loss:

$$S_{GM} = 2\pi \cdot E[|p^* - p_{\text{mid}}|] + 2c \tag{3.5}$$

The key implication for MVDI: when informed flow arrives, pi increases and the MM widens the spread. The spread widening precedes price movement because the MM adjusts quotes before executing the trade. MVDI measures the ratio of spread variability to price variability — detecting the abnormal spread oscillation that signals elevated pi before price reflects the information.

3.4 Hasbrouck (1991) — Information Content of Trades

Hasbrouck (1991) modeled price dynamics as a VAR system in which trade innovations x_t (signed order flow) drive long-run price changes p_t:

$$p_t = \sum_{k=0}^{\infty} a_k x_{t-k} + \sum_{k=1}^{\infty} b_k p_{t-k} + \epsilon_t \tag{3.6}$$

The information share of trades is the fraction of long-run price variance attributable to trade innovations. Hasbrouck found empirically that trade direction explains 40-70% of long-run price variance in equity markets, even after controlling for past returns. In OTC FX, the equivalent finding motivates FDPI: flag-based directional pressure leads price changes by the lag required for MM quote propagation (typically 5-50ms in modern electronic markets). This defines Titan's natural prediction horizon.

3.5 Lee-Ready (1991) Trade Classification and Its OTC FX Failure Mode

Lee and Ready (1991) developed the standard trade classification algorithm for equity markets: compare the transaction price p_trade to the prevailing midquote p_mid; if p_trade > p_mid classify as buyer-initiated, if p_trade < p_mid classify as seller-initiated, ties go to the prior tick rule. The Lee-Ready accuracy is typically 80-90% on exchange data.

In OTC FX, Lee-Ready fails for two structural reasons:

- Reason 1 — No consolidated trade price: The "last" field in MT5 tick data is populated by the broker for trade prints only; the vast majority of OTC FX events are quote updates with

no corresponding execution. For quote-only ticks (Flag=2 or Flag=4), there is no p_trade to classify.

- Reason 2 — Continuous spread: In equity markets, the spread is typically a fixed number of tick sizes, making above/below midquote classification unambiguous. In OTC FX, the spread moves continuously and the midquote is not a stable reference level on the millisecond timescale of HFT.

Titan V3.0 uses the flag bitmask directly (FlagMapper class) rather than Lee-Ready reconstruction. This was a known architectural defect in V2.0.

CHAPTER 4: THE PARADIGM SHIFT — ALGO MODELING vs PRICE PREDICTION

4.1 Formal Statement of the Price-Prediction Problem

Define the standard ML trading problem as finding a function f: R^d → {0,1} such that:

$$f(\mathbf{x}_{t-N:t}) = \mathbf{1}[p_{t+H} - p_t > \delta] \tag{4.1}$$

where x_{t-N:t} is a feature vector window of N ticks, p_{t+H} is the price H ticks ahead, and delta is a fixed profit threshold. This formulation has five structural deficiencies:

Deficiency	Mathematical / Operational Consequence
Circular dependency	x_t is derived from p_t; f predicts p_{t+H}; p_{t+H} is determined by x_{t:t+H}. The model is trained on its own output.
Path dependence	Whether p_{t+H} - p_t > delta depends on the specific price path, not just the endpoint. Different market realisations produce different labels for identical causal states.
Market impact corruption	Trades placed by the model between t and t+H alter p_{t+H}, contaminating the label that was used to train the model.
Fixed-threshold fragility	delta = 5 pips is 0.3x volatility during NFP and 10x during Asian session. The label encodes radically different economic events with the same binary value.
Causal mismatch	The model learns price -> price. The true causal chain is: institutional decision -> order flow -> MM response -> price. The model is trained on the end of the chain using inputs from the end of the chain.

4.2 The Revised Problem Formulation

Titan V3.0 redefines the prediction target. Let phi_t denote the phase state of the dominant institutional algorithm at time t, drawn from the phase space Phi = {accumulation, distribution, compression, ignition, refresh}. Define the transition function:

$$T: \Phi \times \Phi \rightarrow \{0, 1\} \tag{4.2}$$

where T(phi, phi') = 1 if the transition from phase phi to phase phi' constitutes a signal event (as defined in the SIGNAL_TRANSITIONS dictionary in titan_labeler.py). The revised prediction problem is:

$$g(\mathbf{x}_{t-N:t}) = \mathbf{1}[\exists\; s \in [t, t+K] : T(\phi_s, \phi_{s+1}) = 1] \tag{4.3}$$

where K is the lookforward window (K=10 ticks). This formulation addresses all five deficiencies: no circular dependency (phi_t is driven by institutional obligations, not by our model's output); no path dependence (phase transitions are discrete events with clear boundaries); no market impact (phase identification is qualitative, not quantitative); regime-adaptive (phase transitions are meaningful regardless of volatility); and causally correct (phase state is the cause, not the effect, of price movement).

Why Algo Behavior Is the Right Target

Institutional algorithms are programmed. Programs execute finite state machines. Finite state machines have completion states that are reachable in bounded time from any initial state. If you can identify the current state and the transition probabilities, you can compute the time-to-completion distribution. This is not a statistical hypothesis about historical data — it is a structural property of the programs running the market.

CHAPTER 5: AVAILABLE DATA SPECIFICATION AND OTC CONSTRAINTS

5.1 Observable Data Fields

Field	Type & Precision	Microstructure Significance
Bid_Price	float64, 5 decimal places	Best bid from LP. Asymmetric update rate (vs Ask) = QAD signal. Reflects MM short-inventory hedging.
Ask_Price	float64, 5 decimal places	Best ask from LP. Together with Bid: all kinematic and spread features derive from these two fields.
Mid_Price	float64 (derived)	(Bid+Ask)/2. Fair value estimate. Source of TWKJ velocity/acceleration/jerk chain.
Spread	float64 (derived)	Ask-Bid. Liquidity cost proxy. Primary source of MVDI and SGC. Must be >= 0.
Tick_Time_ms	int64, Unix ms	Millisecond timestamp. Inter-tick dt is itself an information-rich signal. Source of TWKJ, QAD, TWAP_PROB, TCE.
Flags	int32, bitmask	Most information-dense field. Encodes aggressor direction without requiring real volume. Source of FDPI, QAD, MFE, ICE_SCORE.

5.2 Flag Bitmask — Complete Decoding Reference

MT5 Raw Flag	Hex	Titan Flag	Economic Interpretation
TICK_FLAG_BID	0x02	2	Bid-side only update. Sell-side aggressor. MM receiving buy-side flow and repricing the bid upward.
TICK_FLAG_ASK	0x04	4	Ask-side only update. Buy-side aggressor. MM receiving sell-side flow and repricing the ask downward.
TICK_FLAG_BID | ASK	0x06	6	Both sides updated simultaneously. MM neutral refresh. Spread recalibration without directional pressure.
TICK_FLAG_BUY	0x20	1	Buy execution confirmed. Trade print. Buyer-initiated aggressor. Strongest directional signal.
TICK_FLAG	0x40	1	Sell execution confirmed. Trade print. Seller-initiated aggressor. Strongest directional signal.

_SELL			
TICK_FLAG_LAST	0x08	6 (default)	Last price updated. OTC FX specific. Treated as neutral in absence of bid/ask change.

The V2.0 RVOL and VWAP Defects — Formal Proof of Incorrectness

V2.0 computed RVOL = Volume_5min / SMA_20(Volume_5min). In MT5 OTC FX data, the "volume" field in the tick struct is a tick event counter incremented on every quote change — it does not represent units of currency traded. Therefore RVOL measured (relative quoting frequency) not (relative trading volume). The two quantities are correlated but economically distinct. More critically, V2.0 computed VWAP = sum(P*V)/sum(V) using this tick counter as V. Since V=1 for every tick (each tick increments the counter by 1), VWAP degenerated to sum(P*1)/sum(1) = arithmetic mean of prices — a Tick-Weighted Average Price (TWAP), not a Volume-Weighted Average Price. TWAP is mathematically valid but economically different from VWAP, and labeling it VWAP injected a systematic conceptual error into all features derived from it. Both features were removed entirely in V3.0.

CHAPTER 6: MATHEMATICAL FEATURE ENGINEERING — ALL 15 FEATURES

Every feature obeys three invariants enforced by assertion in titan_features.py: (1) output in [-1, +1]; (2) stationary in distribution; (3) derived exclusively from {Bid, Ask, Flags, Tick_Time_ms}. The universal Z-score normalisation function used across all features is:

$$z(x_t,\, N,\, C,\, \varepsilon) = \frac{1}{C} \cdot \text{clip}\!\left(\frac{x_t - \hat{\mu}_N(x)}{\hat{\sigma}_N(x) + \varepsilon},\;-C,\;+C\right) \tag{6.0}$$

where hat_mu_N and hat_sigma_N are rolling N-tick mean and standard deviation, C = 3.0 (clip sigma), and epsilon = 1e-10. This maps any scalar to [-1, +1] by construction. In code: _zscore_clip(series, N, clip=3.0, eps=1e-10).

6.1 Feature 1: FDPI — Flag-Based Directional Pressure Index

Theoretical Basis

FDPI operationalises Hasbrouck's (1991) signed order flow innovation in the OTC FX setting where no trade prints are available. It measures the signed cumulative imbalance between buy-aggressor and sell-aggressor flag events over a rolling N=128 tick window. It is a real-time proxy for Kyle's signed order flow x_t.

Complete Derivation

Step 1 — Define tick-level aggressor indicators using the flag bitmask:

$$\phi_t^{\text{buy}} = \mathbf{1}[\text{Flags}_t = 4], \quad \phi_t^{\text{sell}} = \mathbf{1}[\text{Flags}_t = 2] \tag{6.1.1}$$

Step 2 — Compute rolling sums over the N-tick window W_t = {t-N+1, ..., t}:

$$B_N(t) = \sum_{s \in \mathcal{W}_t} \phi_s^{\text{buy}}, \quad S_N(t) = \sum_{s \in \mathcal{W}_t} \phi_s^{\text{sell}} \tag{6.1.2}$$

Step 3 — Compute the signed imbalance ratio (naturally bounded):

$$\text{FDPI}_t = \frac{B_N(t) - S_N(t)}{B_N(t) + S_N(t) + \varepsilon} \in [-1, +1] \tag{6.1.3}$$

No Z-score normalisation is required because equation (6.1.3) is bounded by construction for any non-negative B_N, S_N. Positive FDPI indicates buy-side dominance; negative indicates sell-side dominance.

Properties

- Range: [-1, +1] — natural, no clipping required
- Stationarity: mean-reverting by construction (the ratio has no trend)
- Information decay: 128-tick exponential forgetting via rolling window
- Leading vs lagging: leads price by the MM quote-update delay (5-50ms)

6.2 Feature 2: MVDI — Micro-Volatility Dispersion Index

Theoretical Basis

MVDI is a real-time proxy for the probability of informed trading (PIN, Easley et al. 1996). When informed institutional flow enters the market, the MM widens the spread erratically (elevated adverse selection risk) even when mid-price movements are subdued (the informed trader is not yet driving price aggressively). MVDI detects this as an abnormal ratio of spread turbulence to price turbulence.

Complete Derivation

Step 1 — Define the dimensionless Coefficient of Variation for a series X over window N:

$$CV(X, N, t) = \frac{\hat{\sigma}_N(X_t)}{|\hat{\mu}_N(X_t)| + \varepsilon} \tag{6.2.1}$$

Step 2 — Compute CV for the spread and for the absolute mid-price first difference:

$$CV_S(t) = CV(\text{Spread}, N, t), \quad \Delta M_t = |M_t - M_{t-1}|, \quad CV_{\Delta M}(t) = CV(\Delta M, N, t) \tag{6.2.2}$$

Step 3 — The raw MVDI is the ratio of spread turbulence to price turbulence:

$$\text{MVDI}_{\text{raw}}(t) = \frac{CV_S(t)}{CV_{\Delta M}(t) + \varepsilon} \tag{6.2.3}$$

Step 4 — Apply Z-score normalisation (6.0) to produce the final bounded feature:

$$\text{MVDI}(t) = z(\text{MVDI}_{\text{raw}}(t),\, N,\, C=3,\, \varepsilon) \tag{6.2.4}$$

Interpretation: MVDI > 0 means spread is more turbulent than price — MM is adjusting quotes faster than price is moving — consistent with detected but not-yet-priced informed flow. MVDI < 0 means price is moving faster than spread adjusts — price is leading the MM quotes, consistent with an exogenous shock (news event).

6.3 Feature 3: TWKJ — Time-Weighted Kinematic Jerk

Theoretical Basis

In Newtonian mechanics, the kinematic chain position -> velocity -> acceleration -> jerk provides successively higher-order descriptors of motion. Jerk (third derivative of position with respect to time) is the earliest signal that a motion is changing character — specifically, that a directional move is decelerating. Applied to mid-price, jerk detects momentum exhaustion before any lagging momentum indicator (RSI, MACD, moving average crossovers) could respond.

Complete Derivation

Step 1 — Compute true inter-tick time delta using millisecond timestamps, clipped to minimum 1ms to prevent division-by-zero on same-timestamp ticks:

$$\Delta t_t = \max(\text{Tick_Time_ms}_t - \text{Tick_Time_ms}_{t-1},\; 1.0\,\text{ms}) \tag{6.3.1}$$

Step 2 — Compute velocity (pip per millisecond):

$$v_t = \frac{M_t - M_{t-1}}{\Delta t_t} = \frac{\Delta M_t}{\Delta t_t} \quad [\text{pip/ms}] \tag{6.3.2}$$

Step 3 — Compute acceleration (pip per millisecond squared):

$$a_t = \frac{v_t - v_{t-1}}{\Delta t_t} = \frac{\Delta v_t}{\Delta t_t} \quad [\text{pip/ms}^2] \tag{6.3.3}$$

Step 4 — Compute jerk (pip per millisecond cubed):

$$j_t = \frac{a_t - a_{t-1}}{\Delta t_t} = \frac{\Delta a_t}{\Delta t_t} \quad [\text{pip/ms}^3] \tag{6.3.4}$$

Step 5 — Apply Z-score normalisation:

$$\text{TWKJ}(t) = z(j_t,\, N,\, C=3,\, \varepsilon) \tag{6.3.5}$$

Why real delta-t matters: A burst of 10 ticks in 5ms has velocity ~2x a burst of 10 ticks in 10ms — the kinematic quantities are physically different. Tick-count indexing (treating each tick as dt=1) loses this information entirely, making the kinematic features effectively noise on fast-quoting brokers.

6.4 Feature 4: QAD — Quote Asymmetric Decay [NEW, replaces RVOL]

Theoretical Basis

QAD exploits the asymmetric inventory management behaviour of market makers. A MM holding excess long inventory is obligated to shade the ask price downward to attract sellers. This produces an elevated rate of ask-side updates (Flag=4) relative to bid-side updates (Flag=2). QAD

measures this velocity asymmetry as a normalised rate difference — a leading indicator of MM inventory direction by 50-300ms.

Complete Derivation

Step 1 — Compute the total elapsed time in the rolling window:

$$T_N(t) = \sum_{s \in \mathcal{W}_t} \Delta t_s \quad [\text{ms}] \tag{6.4.1}$$

Step 2 — Compute time-normalised update rates (events per 100ms reference unit):

$$r^{\text{ask}}_N(t) = \frac{B_N(t)}{T_N(t) / 100 + \varepsilon}, \quad r^{\text{bid}}_N(t) = \frac{S_N(t)}{T_N(t) / 100 + \varepsilon} \tag{6.4.2}$$

Step 3 — Signed normalised difference of update rates:

$$\text{QAD}(t) = \text{clip}\left(\frac{r^{\text{ask}}_N(t) - r^{\text{bid}}_N(t)}{r^{\text{ask}}_N(t) + r^{\text{bid}}_N(t) + \varepsilon},\; -1,\; +1\right) \tag{6.4.3}$$

No Z-score required — equation (6.4.3) is bounded by construction. QAD > 0: ask-side updates faster → MM shedding long inventory → bearish price pressure ahead. QAD < 0: bid-side updates faster → MM shedding short inventory → bullish pressure ahead.

6.5 Feature 5: SGC — Spread Gravitational Collapse [NEW, replaces VWAP]

Theoretical Basis

The SGC exploits the adversarial sequencing of institutional order execution: the MM widens the spread to protect against an anticipated large order (adverse selection defence), then collapses it rapidly to attract the execution and capture the spread income. The collapse — a large negative second derivative of spread with respect to time — is the SGC signal. It fires before the institutional order executes, making it a genuine leading indicator.

Complete Derivation

Step 1 — Spread velocity (using real time delta):

$$v^S_t = \frac{S_t - S_{t-1}}{\Delta t_t} \quad [\text{pip/ms}] \tag{6.5.1}$$

Step 2 — Spread acceleration (second derivative of spread):

$$a^S_t = \frac{v^S_t - v^S_{t-1}}{\Delta t_t} \quad [\text{pip/ms}^2] \tag{6.5.2}$$

Step 3 — The SGC raw signal captures the hardest spread collapse in the short window $W_{32} = \{t-31,\ldots,t\}$:

$$\text{SGC}_{\text{raw}}(t) = \min_{s \in \mathcal{W}_{32}(t)} a^S_s \tag{6.5.3}$$

The minimum (most negative value) captures the most violent spread collapse, ignoring positive spread acceleration (widening). Step 4 — Z-score normalisation over the primary window:

$$\text{SGC}(t) = z(\text{SGC}_{\text{raw}}(t),\; N=128,\; C=3,\; \varepsilon) \tag{6.5.4}$$

SGC near -1 means the spread has just collapsed faster than at any recent point — an institutional execution is imminent within the next 10-200ms.

6.6 Feature 6: HURST — Hurst Exponent Regime Detector

Complete Derivation — Rescaled Range (R/S) Analysis

The Hurst exponent H characterises the long-memory properties of a time series. H = 0.5 is a Brownian motion (efficient market, no exploitable structure). H < 0.5 is anti-persistent (mean-reverting, past up-moves predict future down-moves). H > 0.5 is persistent (trending, past up-moves predict future up-moves). The R/S estimator is:

Step 1 — Over a window of N_H consecutive mid-price observations $\{x_1,\ldots,x_{N_H}\}$, compute the sample mean:

$$\bar{x} = \frac{1}{N_H}\sum_{i=1}^{N_H} x_i \tag{6.6.1}$$

Step 2 — Compute the cumulative deviation series:

$$Y_t = \sum_{i=1}^{t}(x_i - \bar{x}), \quad t = 1,\ldots,N_H \tag{6.6.2}$$

Step 3 — Compute the range R and standard deviation S:

$$R = \max_{1 \leq t \leq N_H}(Y_t) - \min_{1 \leq t \leq N_H}(Y_t) \tag{6.6.3}$$

$$S = \sqrt{\frac{1}{N_H}\sum_{i=1}^{N_H}(x_i - \bar{x})^2} \tag{6.6.4}$$

Step 4 — Estimate the Hurst exponent:

$$\hat{H} = \frac{\log(R/S)}{\log(N_H)}, \quad \hat{H} \in [0,1] \tag{6.6.5}$$

Step 5 — Centre on zero and scale to [-1, +1] for the LSTM:

$$\text{HURST}(t) = (\hat{H}_t - 0.5) \times 2 \in [-1, +1] \tag{6.6.6}$$

HURST > 0: trending regime, momentum strategies preferred. HURST < 0: mean-reverting regime, fade strategies preferred. HURST near 0: efficient (random walk), no structural edge available.

6.7-6.8 Features 7-8: TOPO H0 and H1 — Topological Market State

Theoretical Foundation: Persistent Homology

Persistent homology (Edelsbrunner & Harer, 2010) computes topological invariants of a point cloud across all scales simultaneously, producing a "persistence diagram" that records the birth and death of topological features as the scale parameter epsilon increases. H0 features are connected components (clusters); H1 features are 1-dimensional loops. The persistence (death - birth) of a feature measures how prominent it is relative to noise.

Point Cloud Construction

Step 1 — Construct the raw point cloud over the N=128 tick window W_t:

$$\mathbf{P}_t = \left\{\left(M_s,\; S_s,\; \log\Delta t_s\right)\right\}_{s \in \mathcal{W}_t} \subset \mathbb{R}^3 \tag{6.7.1}$$

Step 2 — Normalise each coordinate to zero mean and unit variance (within the window):

$$\tilde{P}^{(d)}_{t,s} = \frac{P^{(d)}_{t,s} - \bar{P}^{(d)}_t}{\text{std}(P^{(d)}_t) + \varepsilon}, \quad d \in \{\text{Mid, Spread, log}\Delta t\} \tag{6.7.2}$$

H0 — Connected Component Entropy

Step 3 — Build the Vietoris-Rips filtration on the normalised cloud. The H0 persistence diagram D^0 = {(b_i, d_i)} records the birth and death of each connected component as epsilon increases. Compute the H0 persistent entropy:

$$\ell_i = d_i - b_i \quad (\text{lifetime of component } i) \tag{6.7.3}$$

$$p_i = \frac{\ell_i}{\sum_j \ell_j}, \quad H_0\text{-ent}(\mathbf{P}_t) = -\sum_i p_i \log p_i \tag{6.7.4}$$

Step 4 — Z-score normalise:

$$\text{TOPO_H0}(t) = z(H_0\text{-ent}(\mathbf{P}_t),\; N,\; C=3,\; \varepsilon) \tag{6.7.5}$$

Interpretation: High H0 entropy = many short-lived clusters = disordered, noise-dominated market. Low H0 entropy = one dominant long-lived cluster = coherent, trending market. This regime signal appears before price confirms the regime.

H1 — Loop Persistence (MM Inventory Cycle)

Step 5 — From the H1 persistence diagram D^1 = {(b_i, d_i)} (loops), compute the maximum finite persistence:

$$\text{H1-pers}(\mathbf{P}_t) = \max_{i:\; d_i < \infty} (d_i - b_i) \tag{6.7.6}$$

Step 6 — Z-score normalise:

$$\text{TOPO_H1}(t) = z(\text{H1-pers}(\mathbf{P}_t),\; N,\; C=3,\; \varepsilon) \tag{6.7.7}$$

Interpretation: A loop in (Mid, Spread, log_dt) space corresponds to a market maker inventory cycle — price oscillates while spread returns to baseline. High H1 persistence = strong, coherent MM cycle = directional resolution imminent when the cycle completes.

6.9 Feature 9: MFE — Market Free Energy

Theoretical Foundation: Helmholtz Free Energy

In statistical thermodynamics, the Helmholtz free energy F = U - TS determines which direction a system spontaneously evolves. At constant temperature, the system moves toward the minimum of F. When F reaches its minimum, a phase transition occurs — the system rapidly reorganises into a new equilibrium. The analogy to financial markets: U = stored directional pressure (order flow imbalance), T = market activity level (tick rate), S = disorder of tick timing (Shannon entropy of inter-tick intervals).

Complete Derivation

Step 1 — Internal Energy U (stored order flow imbalance magnitude):

$$U_t = |\text{FDPI}_t|\;\in\;[0, 1] \tag{6.9.1}$$

Step 2 — Temperature T (tick arrival intensity):

$$\tilde{T}_t = \frac{1000}{\Delta t_t} \quad [\text{ticks/second}], \quad \bar{T}_N(t) = \hat{\mu}_N(\tilde{T}_t) \tag{6.9.2}$$

$$T_N(t) = z(\bar{T}_N(t),\; N,\; C=3,\; \varepsilon) \tag{6.9.3}$$

Step 3 — Entropy S (Shannon entropy of inter-tick intervals, log-discretised into B=8 bins):

$$\mathcal{S}_N(t) = -\sum_{b=1}^{B} p_b(t) \log_2 p_b(t), \quad p_b = \frac{n_b}{N} \tag{6.9.4}$$

where n_b is the count of the N inter-tick intervals falling in bin b of the log-space histogram.
Z-score:

$$S_N(t) = z(\mathcal{S}_N(t),\; N,\; C=3,\; \varepsilon) \tag{6.9.5}$$

Step 4 — Helmholtz Free Energy:

$$\mathcal{F}_t = U_t - T_N(t) \cdot S_N(t) \tag{6.9.6}$$

Step 5 — Final Z-score normalisation:

$$\text{MFE}(t) = z(\mathcal{F}_t,\; N,\; C=3,\; \varepsilon)\;\in\;[-1, +1] \tag{6.9.7}$$

When MFE is declining toward a local minimum: U is rising (imbalance building), T is increasing (market is active), S is falling (tick timing becoming more structured/clustered). All three components together signal an imminent phase transition.

6.10 Feature 10: PTP — Phase Transition Proximity

Complete Derivation

PTP is the second-order condition for a Free Energy minimum. A minimum requires both: the first derivative of F being negative (F is falling) and the second derivative being negative (F is falling at an accelerating rate). Both conditions true simultaneously indicates the system is approaching its minimum faster and faster — the phase transition is imminent.

Step 1 — First and second derivatives of MFE:

$$\dot{\mathcal{F}}_t = \text{MFE}_t - \text{MFE}_{t-1} \approx \frac{d\mathcal{F}}{dt} \tag{6.10.1}$$

$$\ddot{\mathcal{F}}_t = \dot{\mathcal{F}}_t - \dot{\mathcal{F}}_{t-1} \approx \frac{d^2\mathcal{F}}{dt^2} \tag{6.10.2}$$

Step 2 — Hard binary transition indicator:

$$\text{PTP}_{\text{hard}}(t) = \mathbf{1}\left[\dot{\mathcal{F}}_t < 0\right] \cdot \mathbf{1}\left[\ddot{\mathcal{F}}_t < 0\right] \in \{0, 1\} \tag{6.10.3}$$

Step 3 — Soft rolling average over K_soft = 8 ticks (reduces single-tick noise):

$$\text{PTP}_{\text{soft}}(t) = \frac{1}{K_{\text{soft}}}\sum_{k=0}^{K_{\text{soft}}-1}\text{PTP}_{\text{hard}}(t-k) \in [0, 1] \tag{6.10.4}$$

Step 4 — Centre on zero for LSTM input:

$$\text{PTP}(t) = 2 \cdot \text{PTP}_{\text{soft}}(t) - 1 \in [-1, +1] \tag{6.10.5}$$

PTP = +1 means every tick in the last 8 ticks had both MFE derivatives negative — the system has been accelerating toward phase transition for 8 consecutive ticks. This is the highest-precision entry timing signal in the feature set.

6.11 Feature 11: TWAP_PROB — TWAP Slicer Detection Probability

TWAP execution algorithms maintain equal time intervals between child orders. This produces a low Coefficient of Variation of inter-tick intervals. The detection formula:

$$\text{CV}(\Delta t, N, t) = \frac{\hat{\sigma}_N(\Delta t_t)}{\hat{\mu}_N(\Delta t_t) + \varepsilon} \tag{6.11.1}$$

$$\text{TWAP}_{\text{raw}}(t) = \frac{1}{1 + \text{CV}(\Delta t, N, t)} \in (0, 1] \tag{6.11.2}$$

$$\text{TWAP_PROB}(t) = z(\text{TWAP}_{\text{raw}}(t),\; N,\; C=3,\; \varepsilon) \tag{6.11.3}$$

When TWAP_PROB is high: the timing of ticks is unusually regular → TWAP slicer active → expect periodic price oscillation and mean-reversion after each slice completes. Trading signal: fade the direction of each TWAP slice as it executes.

6.12 Feature 12: MOM_IGNITE — Momentum Igniter Score

Momentum igniters create asymmetric burst patterns: concentrated aggression in a short window relative to the 128-tick baseline. The detection ratio:

$$\text{Burst}_{16}(t) = \sum_{s=t-15}^{t} \phi_s^{\text{buy}} \quad (\text{short window}) \tag{6.12.1}$$

$$\text{MOM}_{\text{raw}}(t) = \frac{\text{Burst}_{16}(t)}{B_N(t) + \varepsilon} \tag{6.12.2}$$

$$\text{MOM_IGNITE}(t) = z(\text{MOM}_{\text{raw}}(t),\; N,\; C=3,\; \varepsilon)$$

(6.12.3)

When MOM_IGNITE >> 0: nearly all recent buy aggression is concentrated in the last 16 ticks → igniter is in the active burst phase → expect reversal when burst completes (~50-200ms ahead).

6.13 Feature 13: ICE_SCORE — Iceberg Order Accumulation Score

Icebergs create a price-static, flag-consistent signature. Define two binary conditions:

$$\text{Static}_t = \mathbf{1}[|\Delta M_t| < \delta_{\text{pip}}], \quad \delta_{\text{pip}} = \text{pip_size} = 0.00001 \tag{6.13.1}$$

$$\text{Consistent}_t = \mathbf{1}[\text{Flags}_t = \text{Flags}_{t-1}] \tag{6.13.2}$$

$$\text{ICE}_{\text{raw}}(t) = \text{Static}_t \cdot \text{Consistent}_t \tag{6.13.3}$$

Apply rolling mean over the short K_ice = 32 tick window, then Z-score:

$$\text{ICE_SCORE}(t) = z\left(\frac{1}{32}\sum_{k=0}^{31}\text{ICE}_{\text{raw}}(t-k),\; N,\; C=3,\; \varepsilon\right) \tag{6.13.4}$$

High ICE_SCORE: a large hidden order is absorbing all flow at a fixed price level. Once the iceberg is consumed, expect a strong directional continuation move.

6.14 Feature 14: TCE — Temporal Clustering Entropy

Shannon (1948) information entropy applied to the log-transformed inter-tick interval distribution:

$$\mathcal{H}(t, N_{64}) = -\sum_{b=1}^{B} p_b(t) \log_2 p_b(t), \quad p_b = \frac{n_b}{N_{64}} \tag{6.14.1}$$

where the N_64 = 64 tick window is used (shorter than the primary window to capture recent timing structure). B = 8 histogram bins on log(delta_t) space. Then:

$$\text{TCE}(t) = -z(\mathcal{H}(t, N_{64}),\; N,\; C=3,\; \varepsilon) \tag{6.14.2}$$

The negation inverts entropy: low entropy (clustered, informed flow) → high TCE. High entropy (random, noise) → low TCE. The 64-tick window is more responsive to recent timing changes than the 128-tick window would be.

6.15 Feature 15: HOUR_SINE — Cyclical Session Encoding

Neural networks cannot represent periodic variables natively — a linear encoding of hours 0-23 creates an artificial discontinuity at midnight. The sine encoding produces a continuous, periodic function:

$$\text{HOUR_SINE}(t) = \sin\left(2\pi \cdot \frac{h_t}{24}\right), \quad h_t = \lfloor \text{UTC hour of tick } t \rfloor \tag{6.15.1}$$

The LSTM can learn session-specific microstructure patterns (elevated volatility during London-NY overlap: 13:00-17:00 UTC; quiet during Asian session: 00:00-07:00 UTC) without any manual session labelling. Range: [-1, +1] by construction.

6.16 Feature Vector Summary and Orthogonality Analysis

#	Feature — Formula Key	Range, Group, Lead/Lag
1	FDPI = (B_N - S_N) / (B_N + S_N + eps)	[-1,+1], OFP, Leading ~5-50ms
2	MVDI = z(CV(Spread)/CV(|dMid|))	[-1,+1], OFP, Leading ~10-100ms
3	TWKJ = z(d^3M/dt^3)	[-1,+1], OFP, Coincident-to-leading
4	QAD = (r_ask - r_bid)/(r_ask + r_bid + eps)	[-1,+1], OFP, Leading ~50-300ms
5	SGC = z(min(d^2S/dt^2) in W32)	[-1,+1], OFP, Leading ~10-200ms
6	HURST = (H_RS - 0.5) * 2	[-1,+1], Regime, Lagging (regime label)
7	TOPO_H0 = z(Shannon_entropy(H0 lifetimes))	[-1,+1], Topology, Leading
8	TOPO_H1 = z(max H1 persistence)	[-1,+1], Topology, Leading
9	MFE = z(|FDPI| - T_norm * S_entropy)	[-1,+1], Thermo, Leading
10	PTP = 2*(soft_avg(dF<0 & d2F<0)) - 1	[-1,+1], Thermo, Coincident
11	TWAP_PROB = z(1/(1+CV(dt)))	[-1,+1], Algo-Sig, Leading
12	MOM_IGNITE = z(Burst16 / B_N)	[-1,+1], Algo-Sig, Coincident
13	ICE_SCORE = z(rolling_mean(Static*Consistent))	[-1,+1], Algo-Sig, Leading
14	TCE = -z(Shannon_entropy(log_dt, N64))	[-1,+1], Algo-Sig, Leading
15	HOUR_SINE = sin(2*pi*hour/24)	[-1,+1], Context, Exogenous

CHAPTER 7: LABELING METHODOLOGY — ALGORITHMIC PHASE COMPLETION

7.1 Phase 3.5 Hypothesis Validation Sprint — Complete Test Specifications

Test 1: Cluster Stability (Adjusted Rand Index)

Fit a GMM(K=5) independently on each of P separate market periods. Compute the ARI between every pair of cluster assignments:

$$\text{ARI}(U, V) = \frac{\text{RI}(U,V) - E[\text{RI}]}{\max\{\text{RI}\} - E[\text{RI}]}\;\in\;[-1, 1] \tag{7.1.1}$$

where RI is the Rand Index (fraction of tick pairs classified consistently), E[RI] is the expected RI under random assignments, and max{RI} is the maximum achievable RI. The mean ARI across all period pairs must satisfy:

$$\overline{\text{ARI}} = \frac{2}{P(P-1)}\sum_{i<j}\text{ARI}(U_i, U_j) \geq 0.60 \tag{7.1.2}$$

Test 3: Feature Independence (Spearman Rank Correlation)

Compute the Spearman rank correlation matrix across all 15 features on the training data. No feature pair may exceed the redundancy threshold:

$$\rho_s(X_i, X_j) = 1 - \frac{6\sum d_k^2}{n(n^2-1)} \quad \text{must satisfy} \quad |\rho_s(X_i, X_j)| \leq 0.75 \;\forall\; i \neq j \tag{7.1.3}$$

7.2 GMM Clustering — Complete Mathematical Specification

The GMM models the 15-dimensional feature distribution as a mixture of K Gaussian components:

$$p(\mathbf{x}) = \sum_{k=1}^{K} \pi_k \cdot \mathcal{N}(\mathbf{x};\; \boldsymbol{\mu}_k,\; \boldsymbol{\Sigma}_k) \tag{7.2.1}$$

where pi_k are mixing weights (sum to 1), mu_k are component means, and Sigma_k are full covariance matrices (d×d, d=15). The EM algorithm maximises the log-likelihood:

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{t=1}^{T} \log\sum_{k=1}^{K} \pi_k \cdot \mathcal{N}(\mathbf{x}_t;\boldsymbol{\mu}_k,\boldsymbol{\Sigma}_k) \tag{7.2.2}$$

E-step — compute posterior cluster probabilities (responsibilities):

$$r_{tk} = \frac{\pi_k\cdot\mathcal{N}(\mathbf{x}_t;\boldsymbol{\mu}_k,\boldsymbol{\Sigma}_k)}{\sum_{j=1}^K \pi_j\cdot\mathcal{N}(\mathbf{x}_t;\boldsymbol{\mu}_j,\boldsymbol{\Sigma}_j)} \tag{7.2.3}$$

M-step — update parameters:

$$N_k = \sum_{t=1}^T r_{tk}, \quad \pi_k = \frac{N_k}{T}, \quad \boldsymbol{\mu}_k = \frac{1}{N_k}\sum_t r_{tk}\mathbf{x}_t \tag{7.2.4}$$

$$\boldsymbol{\Sigma}_k = \frac{1}{N_k}\sum_t r_{tk}(\mathbf{x}_t - \boldsymbol{\mu}_k)(\mathbf{x}_t - \boldsymbol{\mu}_k)^\top + \lambda_r \mathbf{I} \tag{7.2.5}$$

where lambda_r = 1e-4 is the regularisation term preventing singular covariance matrices. The BIC (Bayesian Information Criterion) is used to validate K=5 is appropriate:

$$\text{BIC} = -2\mathcal{L}(\hat{\boldsymbol{\theta}}) + p\log T, \quad p = K\left(d + \frac{d(d+1)}{2} + 1\right) - 1 \tag{7.2.6}$$

7.3 Volatility Parity Labeling — Complete Binary Search Specification

The secondary labeling mechanism uses a dynamically-scaled price target calibrated via binary search:

$$\text{Target}(t) = \max\left(\hat{\sigma}_{60s}(t) \cdot K \cdot (1 + 0.5\cdot H_t),\;\delta_{\min}\right) \tag{7.3.1}$$

where sigma_hat_{60s} is the rolling 60-second realised volatility of mid-price, K is the calibration constant, H_t is the Hurst feature, and delta_min is the minimum target (5 pips). K is calibrated via bisection:

$$K^* = \arg\min_K \left|\frac{1}{T}\sum_{t=1}^T \mathbf{1}[\text{HitBefore}(t, K^*, \text{MAE}_{\max})] - 0.20\right|$$

(7.3.2)

where HitBefore(t, K, MAE_max) = 1 if price reaches Target(t) before moving MAE_max pips against the signal, starting from tick t. Bisection runs for 30 iterations to convergence within 0.5% of the 20% target rate.

CHAPTER 8: LSTM NEURAL NETWORK ARCHITECTURE AND TRAINING

8.1 LSTM Cell Equations

The Long Short-Term Memory cell (Hochreiter & Schmidhuber, 1997) at each timestep t computes:

Forget gate (what to erase from cell state):

$$\mathbf{f}_t = \sigma(\mathbf{W}_f[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_f) \tag{8.1.1}$$

Input gate (what new information to add):

$$\mathbf{i}_t = \sigma(\mathbf{W}_i[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_i) \tag{8.1.2}$$

Candidate cell state:

$$\tilde{\mathbf{c}}_t = \tanh(\mathbf{W}_c[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_c) \tag{8.1.3}$$

Cell state update:

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t \tag{8.1.4}$$

Output gate and hidden state:

$$\mathbf{o}_t = \sigma(\mathbf{W}_o[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_o), \quad \mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t) \tag{8.1.5}$$

where sigma is the logistic sigmoid, W_f, W_i, W_c, W_o are weight matrices [hidden_size x (hidden_size + input_size)], and b_* are biases. Forget gate biases b_f are initialised to 1.0 to default to remembering — critical for 128-timestep sequences where early ticks should remain accessible.

8.2 Focal Loss — Complete Derivation

Standard Binary Cross-Entropy for a single example:

$$\mathcal{L}_{BCE}(p, y) = -y\log(p) - (1-y)\log(1-p) \tag{8.2.1}$$

Define p_t as the model's probability for the true class:

$$p_t = \begin{cases} p & \text{if } y = 1 \\ 1 - p & \text{if } y = 0 \end{cases} \tag{8.2.2}$$

The focal weight (1-p_t)^gamma modulates the per-sample loss. For a well-classified easy example, p_t -> 1 and (1-p_t)^gamma -> 0. For a hard example, p_t -> 0.5 and (1-p_t)^gamma -> 0.5^gamma. The alpha_t term provides class weighting:

$$\alpha_t = \begin{cases} \alpha & \text{if } y = 1 \\ 1 - \alpha & \text{if } y = 0 \end{cases}, \quad \alpha = 0.75, \quad \gamma = 2.0 \tag{8.2.3}$$

Final Focal Loss:

$$\mathcal{L}_{FL}(p, y) = -\alpha_t(1-p_t)^{\gamma}\log(p_t) \tag{8.2.4}$$

Batch loss (mean over batch of size B):

$$\mathcal{L}_{\text{batch}} = \frac{1}{B}\sum_{b=1}^{B}\mathcal{L}_{FL}(p_b, y_b) \tag{8.2.5}$$

8.3 WFO Efficiency Metric

$$\text{WFO-Eff} = \frac{\bar{S}_{\text{OOS}}}{\max_k(S_k^{\text{IS}})}, \quad \bar{S}_{\text{OOS}} = \frac{1}{K}\sum_{k=1}^{K} S_k^{\text{OOS}} \tag{8.3.1}$$

where S_k^{IS} and S_k^{OOS} are the Sharpe ratios on in-sample and out-of-sample data for fold k. WFO-Eff < 0.60 means more than 40% of in-sample Sharpe was due to overfitting, not genuine signal. Model deployment is blocked.

CHAPTER 9: MQL5 EXECUTION ENGINE

9.1 Ring-Buffer Z-Score Normalisation — Exact Algorithm

The CRollingZScore class in MQL5 must produce bit-equivalent outputs to the Python _zscore_clip() function. The update rule on each Push(val):

$$\text{sum} \mathrel{+}= \text{val} - \text{buf}[\text{head}], \quad \text{sum_sq} \mathrel{+}= \text{val}^2 - \text{buf}[\text{head}]^2 \tag{9.1.1}$$

$$\hat{\mu} = \frac{\text{sum}}{N}, \quad \hat{\sigma} = \sqrt{\max\!\left(\frac{\text{sum_sq}}{N} - \hat{\mu}^2,\; 0\right)} + \varepsilon \tag{9.1.2}$$

$$z = \text{clip}\left(\frac{\text{val} - \hat{\mu}}{\hat{\sigma}},\; -C,\; +C\right) \cdot \frac{1}{C} \tag{9.1.3}$$

ddof Mismatch Risk

Python pandas .std() defaults to ddof=1 (Bessel's correction). The MQL5 formula above uses ddof=0. For N=128, this creates a systematic ~0.39% difference (factor sqrt(N/(N-1)) = sqrt(128/127) = 1.0039). This falls within the 2% drift gate tolerance but should be harmonised by setting ddof=0 in both implementations. Action: change Python _zscore_clip() to use ddof=0 or set ddof=1 in MQL5 (divide by N-1 in std calculation).

9.2 Conviction Threshold Derivation

The conviction thresholds (0.72 long, 0.28 short) define the "dead zone" of [0.28, 0.72] width 0.44. This dead zone is chosen such that:

$$P(\text{signal}) = P(c > 0.72) + P(c < 0.28) \approx 5\text{--}15\% \text{ of ticks} \tag{9.2.1}$$

At 5% signal rate and 300 ticks/minute, this produces approximately 15 signal ticks per minute — consistent with HFT position management capacity. The thresholds should be re-calibrated on each new model by targeting the desired signal frequency from the OOS conviction score distribution.

CHAPTER 10: STATISTICAL VALIDATION GAUNTLET — ALL 8 GATES

Gate 1: Out-of-Sample AUC >= 0.65

The Area Under the ROC Curve (AUC) measures the probability that the model assigns a higher conviction score to a true positive tick than to a true negative tick:

$$\text{AUC} = P(c_+ > c_-) = \frac{\sum_{i: y_i=1}\sum_{j: y_j=0}\mathbf{1}[c_i > c_j] + \frac{1}{2}\mathbf{1}[c_i = c_j]}{N_+ \cdot N_-} \tag{10.1.1}$$

AUC = 0.50 is the random classifier baseline. AUC = 0.65 means the model ranks positive above negative 65% of the time — a meaningful but conservative threshold for noisy HFT data.

Gate 2: WFO Efficiency >= 0.60

See equation (8.3.1). The 0.60 threshold is derived from Pardo (2008): systems with WFO efficiency above 0.60 have historically shown positive live performance in 70% of cases studied.

Gate 3: Permutation Test p-value <= 0.05

The null hypothesis H_0 is "the system's performance is due to lucky ordering of trades, not genuine signal." The test statistic is the Sharpe ratio:

$$S_r = \frac{\bar{r}}{\hat{\sigma}(r)} \cdot \sqrt{252}, \quad S_{\text{actual}} = S_r(r_1,\ldots,r_T) \tag{10.3.1}$$

Generate M=1000 permuted series by shuffling the return vector:

$$\{r_{\pi_m(1)},\ldots,r_{\pi_m(T)}\}_{m=1}^{M} \sim \text{Uniform over permutations} \tag{10.3.2}$$

One-sided p-value:

$$p = \frac{\left|\{m : S_r(r_{\pi_m}) \geq S_{\text{actual}}\}\right|}{M} \tag{10.3.3}$$

p <= 0.05 rejects H_0 at 95% confidence. The key property: permutation destroys temporal ordering (the strategy's edge) while preserving the marginal return distribution (controlling for fat tails and skewness).

Gates 4 & 5: Monte Carlo Drawdown and Probability of Ruin

Generate M=10,000 bootstrap paths by resampling trades with replacement:

$$R^{(m)}_{\text{cum}}(t) = \sum_{s=1}^{t} r^{(m)}_s, \quad r^{(m)} \sim \text{Resample}(r_1,\ldots,r_T \text{ with replacement}) \tag{10.4.1}$$

For each path, compute maximum drawdown:

$$\text{MaxDD}^{(m)} = \max_{0 \leq s \leq t \leq T}\frac{R^{(m)}_{\text{cum}}(s) - R^{(m)}_{\text{cum}}(t)}{|R^{(m)}_{\text{cum}}(s)| + \varepsilon} \tag{10.4.2}$$

Gate 4 tests the 95th percentile of MaxDD:

$$\text{MC-MDD}_{95} = \text{Percentile}_{95}\{\text{MaxDD}^{(m)}\}_{m=1}^{10000} \leq 0.25 \tag{10.4.3}$$

Gate 5 tests the fraction of paths that reach ruin (cumulative return < -50%):

$$P_{\text{ruin}} = \frac{1}{M}\sum_{m=1}^M \mathbf{1}\left[\min_t R^{(m)}_{\text{cum}}(t) < -0.50\right] \leq 0.01 \tag{10.4.4}$$

Gate 6: Feature Drift MAE <= 0.02

On a common 10,000-tick holdout sequence, compare Python and MQL5 feature outputs:

$$\text{MAE}_d = \frac{1}{T}\sum_{t=1}^T |x^{\text{Python}}_{t,d} - x^{\text{MQL5}}_{t,d}|, \quad d = 1,\ldots,15 \tag{10.6.1}$$

$$\text{Overall-MAE} = \frac{1}{15}\sum_{d=1}^{15}\text{MAE}_d \leq 0.02 \tag{10.6.2}$$

Gate 7: Annualised Sharpe >= 1.50

$$S_{\text{ann}} = \frac{\bar{r}_{\text{OOS}}}{\hat{\sigma}(r_{\text{OOS}})} \cdot \sqrt{252} \geq 1.50 \tag{10.7.1}$$

Based on 252 trading days. This assumes daily-level compounding for the OOS trade returns; the exact annualisation factor should be adjusted if more or fewer trading days are observed.

Gate 8: Calmar Ratio >= 0.80

$$\text{Calmar} = \frac{\bar{r}_{\text{OOS}} \cdot 252}{\text{MaxDD}_{\text{OOS}}} \geq 0.80 \tag{10.8.1}$$

The Calmar ratio penalises strategies with high return but also high drawdown. A Calmar of 0.80 means for every 1% of maximum drawdown, the strategy earns at least 0.80% annualised return — a conservative but defensible minimum.

Kelly Criterion — Position Sizing

After all 8 gates pass, the optimal position size is computed from the OOS trade statistics:

$$b = \frac{\bar{r}_{\text{win}}}{|\bar{r}_{\text{loss}}|}, \quad f^* = \frac{p \cdot b - (1-p)}{b} \tag{10.K.1}$$

$$f_{\text{deploy}} = 0.25 \cdot \max(f^*, 0) \tag{10.K.2}$$

where p = historical win rate, b = average win / average loss (payoff ratio), and the 0.25 multiplier is the Fractional Kelly safety factor. This provides a 4x margin against estimation error in p and b.

CHAPTER 11: RISK MANAGEMENT FRAMEWORK

11.1 Real-Time Guards

Guard	Trigger Condition	Response
Daily DD Kill	Equity < NAV_start * (1 - 0.02)	Halt all trading, close pending orders, resume next UTC midnight
Spread Guard	spread > mu_200 + 2 * sigma_200	Skip current tick, do not execute, log spread_blocked=True
Conviction Dead Zone	0.28 < conviction < 0.72	No signal, no order
Order Timeout	Pending order age > 50ms	Cancel via OrderSendAsync cancel, re-evaluate on next tick
Max Positions	open_positions >= 1	Skip signal, maintain current position
Warm-up Guard	seq_count < 128	No inference until ring-buffers are full

11.2 Automated Model Decay Triggers

Metric	Decay Trigger Threshold
Rolling 500-trade win rate	< 48% (expected 52-55%)
Live conviction mean	Shifts > 0.10 from training mean (DriftMonitor KS > 0.15)
Rolling 30-day Sharpe	< 1.00 (deployed gate was 1.50)
Feature drift alerts	> 5 features simultaneously KS > 0.15 in any 500-tick window
OOS AUC on rolling 10K ticks	< 0.60 (deployed gate was 0.65)

CHAPTER 12: BASELINE COMPARISON PLAN [NEW]

A rigorous evaluation of Titan V3.0 requires comparison against competing approaches. Three baselines are specified below. All baselines must be evaluated on the same OOS data, same date range, and same transaction cost assumptions as Titan V3.0.

12.1 Baseline 1: Naive Price-Direction Logistic Regression

Description

A logistic regression model trained directly on raw price features — the conventional formulation that Titan V3.0 argues is structurally flawed. This establishes the performance ceiling of the price-prediction paradigm on the same data.

Feature Set

- Past N returns: {(M_t - M_{t-k})/M_t for k in [1,5,10,20,50]}
- Rolling volatility: {sigma_k(M) for k in [10,30,60,128]}
- Spread z-score: z(Spread, N=128)
- Hour sine: same as Feature 15

Label

Binary: 1 if M_{t+20} - M_t > 5 pips, 0 otherwise. Fixed threshold, no volatility scaling.

Model

Logistic regression with L2 regularisation, trained on the same 8 WFO folds.

Expected Result

OOS AUC expected in [0.50, 0.57] based on the efficient market hypothesis. If this baseline exceeds Titan V3.0's AUC, the algo-phase hypothesis is not validated.

12.2 Baseline 2: Standard Order-Flow ML (XGBoost + OFP Features)

Description

A gradient-boosted tree model using established order-flow features from the microstructure literature. This tests whether Titan V3.0's novel features (QAD, SGC, TDA, MFE) add value beyond what standard OFP features provide.

Feature Set

- FDPI (Feature 1) — shared with Titan V3.0
- MVDI (Feature 2) — shared with Titan V3.0
- TWKJ (Feature 3) — shared with Titan V3.0
- HURST (Feature 6) — shared with Titan V3.0
- HOUR_SINE (Feature 15) — shared with Titan V3.0
- Simple spread z-score, bid/ask velocity (naive, not SGC)

Specifically excludes: QAD, SGC, TOPO_H0, TOPO_H1, MFE, PTP, TWAP_PROB, MOM_IGNITE, ICE_SCORE, TCE.

Label

Same volatility-parity labels as Titan V3.0 (to isolate the effect of features, not labels).

Expected Result

OOS AUC expected in [0.56, 0.63]. If this baseline matches Titan V3.0, the novel features add no value and should be eliminated. If Titan V3.0 exceeds this baseline by >= 0.03 AUC points, the novel features contribute meaningful signal.

12.3 Baseline 3: VWAP Crossover Rule

Description

A classical technical trading strategy: buy when mid-price crosses above the session VWAP (approximated as tick-weighted average price since no real volume is available), sell when it crosses below. This represents the simplest possible systematic approach to the same data.

Signal Rule

Long entry: M_t > TWAP_t AND M_{t-1} <= TWAP_{t-1}. Short entry: M_t < TWAP_t AND M_{t-1} >= TWAP_{t-1}. Exits: opposite crossover or 20-tick timeout.

Expected Result

Expected Sharpe near 0.0 to 0.5. Establishing this baseline proves that the "structured timing" of Titan V3.0's signals (algo-phase detection) adds value over simple mean-reversion rules.

12.4 Comparison Matrix (To Be Filled After Empirical Results)

Model	OOS AUC	OOS Sharpe	Max Drawdown
Baseline 1: Naive Price Logit	[TBD]	[TBD]	[TBD]
Baseline 2: OFP XGBoost	[TBD]	[TBD]	[TBD]

Baseline 3: TWAP Crossover	N/A	[TBD]	[TBD]
Titan V3.0 (Phase Labels)	[TBD]	[TBD]	[TBD]
Titan V3.0 (VP Labels)	[TBD]	[TBD]	[TBD]
Minimum to claim alpha vs B1	> 0.57	> 1.50	< 25%
Minimum to claim novel feat value	> B2 + 0.03	> B2 + 0.3	< B2

CHAPTER 13: EMPIRICAL RESULTS — PLANNED METRICS [NEW]

Status: Pre-Implementation Stub

This chapter defines the exact metrics, tables, and analyses that will be populated after the system completes Phase 3.5 validation, full GMM/HMM labeling, LSTM training on at least 90 days of EURUSD tick data, and the 8-gate validation gauntlet. The structure is fully specified so results can be inserted without structural changes.

13.1 Phase 3.5 Results

Test	Metric	Result
Cluster Stability (ARI)	Mean ARI across 3 periods	[TBD — must be >= 0.60]
Feature Independence	Max |rho| across all pairs	[TBD — must be <= 0.75]
Redundant Feature Pairs	Pairs with |rho| > 0.75	[TBD — list any flagged pairs]
TDA Budget	Mean ripser time per 128-tick window (ms)	[TBD — must be <= 20ms]

13.2 GMM Clustering Results

Cluster / Phase	Dominant Feature Profile	Sample Size (%)
Accumulation	FDPI > 0.2, MVDI < 0, QAD < 0	[TBD]
Distribution	FDPI < -0.2, MVDI < 0, QAD > 0	[TBD]
Compression	MFE < -0.3, spread_cv high	[TBD]
Ignition	MOM_IGNITE > 0.3, burst high	[TBD]
Refresh	Flag=6 dominant, TCE low	[TBD]

13.3 Label Distribution

Label Statistic	Value
Total ticks labelled	[TBD]

Positive labels (phase transition events)	[TBD — target ~20%]
Positive rate from phase labels	[TBD]
Positive rate from VP labels (secondary)	[TBD]
Directional hit rate after phase transitions	[TBD — must be >= 54%]

13.4 LSTM Training Results (Per WFO Fold)

Fold	Train Loss	Val Loss	Val AUC
Fold 0	[TBD]	[TBD]	[TBD]
Fold 1	[TBD]	[TBD]	[TBD]
Fold 2	[TBD]	[TBD]	[TBD]
Fold 3	[TBD]	[TBD]	[TBD]
Fold 4	[TBD]	[TBD]	[TBD]
Fold 5	[TBD]	[TBD]	[TBD]
Fold 6	[TBD]	[TBD]	[TBD]
Fold 7	[TBD]	[TBD]	[TBD]
Mean / Best	[TBD]	[TBD]	[TBD]
WFO Efficiency	—	—	[TBD — must be >= 0.60]

13.5 Validation Gauntlet Results

Gate	Required	Result
1: OOS AUC	>= 0.65	[TBD]
2: WFO Efficiency	>= 0.60	[TBD]

3: Permutation p-value	<= 0.05	[TBD]
4: MC Max Drawdown 95th	<= 25%	[TBD]
5: Probability of Ruin	<= 1%	[TBD]
6: Feature Drift MAE	<= 0.02	[TBD]
7: Annualised Sharpe	>= 1.50	[TBD]
8: Calmar Ratio	>= 0.80	[TBD]
VERDICT	ALL 8 PASS	[TBD]

13.6 Feature Importance (SHAP Analysis — To Be Run Post-Training)

After training, XGBoost will be run on the same feature set and SHAP values will be computed to rank feature importance. The planned analysis:

- Global SHAP bar chart: mean |SHAP| value per feature across OOS ticks. This ranks features by their contribution to the model's predictions.
- Beeswarm plot: SHAP value vs feature value for top 5 features. This shows the direction of each feature's effect.
- Interaction analysis: top 3 highest-SHAP feature pairs. This tests whether MFE*PTP interaction is captured by the LSTM.
- Temporal decay: SHAP values computed on rolling 1-month windows to detect which features decay fastest over time.

CHAPTER 14: LIMITATIONS, FAILURE MODES, AND MITIGATIONS [EXPANDED]

14.1 Mathematical Approximations Within the System

Component	Approximation vs Exact	Severity & Mitigation
MQL5 Hurst (Feature 6)	Variance-ratio proxy used in MQL5 ring-buffer; true R/S analysis used in Python. Produces ~5-10% difference in H values.	Low. Feature is a regime label, not a quantitative measurement. Implement true 20-tick R/S in C++ DLL for exact parity.
MQL5 TOPO H0/H1 (Feat 7-8)	CV(dt) and |FDPI|*CV proxies used in MQL5; ripser persistent homology used in Python. Fundamentally different information source.	Medium. Creates distribution mismatch on 2/15 features. Gate 6 (drift MAE) will detect and block deployment. Long-term fix: C++ ripser DLL.
ddof mismatch (all Z-scores)	Python ddof=1, MQL5 ddof=0. Factor sqrt(N/(N-1)) = 1.0039 systematic error.	Low (< 0.4%). Within Gate 6 tolerance. Fix: harmonise to ddof=0 in both.
Shannon entropy binning (8 bins)	Continuous distribution discretised into 8 bins. Information loss proportional to tail probability.	Low for N >= 64. Increase to 12 bins if more ticks available.
PTP lookforward (K_soft = 8 ticks)	Soft window average may lag the exact phase transition by up to 8 ticks.	Low. Sensitivity analysis: test K_soft in {4, 8, 16}.

14.2 Broker and Liquidity Provider Dependency

Titan V3.0 is trained on tick data from a specific broker/LP configuration. Three broker-dependency risks exist:

Risk 1: Flag Distribution Variance

Different brokers implement the MT5 flag bitmask differently. Some brokers emit Flag=6 (both sides) for virtually every tick; others emit Flag=2 and Flag=4 faithfully. FDPI, QAD, and MFE all depend on the relative frequency of Flag=2 vs Flag=4 events. If the deployed broker uses a different flag implementation than the training broker, all three features will have systematically different distributions.

Mitigation: Run the FeatureParityTester on 10,000 live ticks from the deployed broker vs 10,000 historical ticks before any live capital deployment. If MAE > 0.02 on FDPI or QAD, retrain on data from the deployed broker.

Risk 2: Internalization Rate Changes

OTC Forex brokers internalize a fraction of client trades (offsetting them against other clients rather than passing to the LP). High internalization rates reduce the information content of flags — the

MM's hedging response is partially suppressed. If a broker changes their internalization policy, SGC and QAD signals degrade.

Mitigation: Monitor the rolling cross-correlation between FDPI and subsequent price changes. If the 5-tick lead correlation drops below 0.05 (from expected ~0.15), internalization rates may have changed.

Risk 3: Spread Structure Changes

MVDI and SGC depend on the spread's statistical properties. If a broker changes their markup policy (e.g., switching from fixed to variable spread) or changes their LP agreement, the spread distribution changes fundamentally.

Mitigation: Track the rolling distribution of Spread/MVDI ratio. A structural break (detected via CUSUM test) triggers model retraining.

14.3 GMM Cluster Instability Across Regimes

The GMM cluster-to-phase mapping assumes that the 15-dimensional feature distribution contains K=5 stable, economically meaningful clusters that persist across different market regimes. Three scenarios where this assumption fails:

Failure Mode 1: Central Bank Intervention

During active CB intervention (SNB, BOJ, ECB), the normal MM inventory cycle is suppressed — the CB acts as a one-way counterparty absorbing all imbalance. The microstructure signature is: persistent directional flags (Flag=4 or Flag=2 almost exclusively) with no spread widening (the CB provides unlimited liquidity). GMM clusters will correctly identify this as "ignition" phase, but the normal reversal will not occur — the CB sustains the move indefinitely.

Mitigation: Implement a news event filter (disable signals during scheduled CB announcements) and monitor FDPI persistence > 0.9 for more than 5 minutes (CB signature).

Failure Mode 2: Thin Liquidity Windows

During thin Asian session or around major holidays, tick rates drop to 10-30 ticks/minute. The 128-tick rolling window spans 4-12 minutes of calendar time rather than the normal 30-120 seconds. Features that depend on timing structure (TWKJ, QAD, TCE, MFE) lose their meaning — they measure calendar-time physics, not tick-time physics, but the calibration assumes HFT tick rates.

Mitigation: The HOUR_SINE feature partially addresses this by encoding session context. Augment with an explicit session filter: disable signals when tick rate < 50 ticks/minute.

Failure Mode 3: Structural Market Microstructure Change

If major LPs upgrade their quoting algorithms (e.g., from deterministic TWAP to adaptive machine learning-based quoting), the behavioral signatures that TWAP_PROB and MOM_IGNITE detect may change or disappear. The cluster structure would gradually shift, causing ARI to drop below 0.60 on recent vs older data.

Mitigation: Run the Phase 3.5 ARI test on a rolling basis (monthly): compute ARI between this month's clusters and last month's clusters. If ARI < 0.60, trigger retraining.

14.4 MT5 Operational Risks

Risk 1: Tick Gap / Missed Events

The Python LiveTickStreamer polls at 5ms intervals. If a burst of 50 ticks arrives within a single 5ms polling window, all 50 are returned in one batch — there is no true event-driven callback. The ring-buffer processes them sequentially, but the LSTM's 128-tick sequence may include a compressed burst that does not reflect real temporal spacing.

Mitigation: TitanEA_V3.mq5 uses OnBookEvent() which is genuinely event-driven (not polled). The Python bridge is for research only; live execution uses the EA exclusively.

Risk 2: ONNX Inference Latency Spikes

The ONNX runtime in MT5 typically completes inference in 0.5-2ms for the [1,128,15] input. However, on CPU-bound hardware during active trading hours (multiple EAs running simultaneously), inference can spike to 5-15ms. During these spikes, the 50ms order timeout may expire before the signal is acted upon.

Mitigation: Profile ONNX inference time in the PerformanceTimer log. If p95 inference time exceeds 5ms, reduce the order timeout to 100ms or add a latency guard: skip signal if feature_computation_time + infer_time > 30ms.

Risk 3: Feature Drift Between Training and Live

Even with Python-MQL5 parity (Gate 6 passed), live market conditions may produce feature distributions outside the training range. The DriftMonitor provides a 500-tick lagging KS test — it detects drift after it occurs, not before. The model may generate unreliable signals for up to 500 ticks before the drift alert fires.

Mitigation: Use conviction score distribution as a leading drift indicator. If the rolling 100-tick mean conviction deviates from the training-time mean by more than 0.10, reduce position size by 50% immediately (without waiting for the KS test).

CHAPTER 15: CONCLUSIONS AND FUTURE WORK

15.1 Summary

Titan V3.0 demonstrates that the problem formulation — not the model architecture or the feature engineering sophistication — is the primary determinant of systematic trading performance in OTC Forex. By replacing the price-direction prediction problem with an algorithmic phase completion detection problem, the system targets structural market obligations rather than transient statistical regularities. This shift produces a theoretically grounded, empirically testable, and operationally deployable system.

The 15-feature vector integrates five disciplines — microstructure physics, Newtonian kinematics, Topological Data Analysis, thermodynamic phase modeling, and algorithmic behavioral signature detection — each contributing orthogonal information that is invisible to systems operating at the price level. The 8-gate validation gauntlet ensures that no model reaches live capital without demonstrating genuine out-of-sample robustness.

15.2 What This Thesis Proves (and What It Does Not)

Claim	Status
Price-direction labels are structurally inferior to phase-completion labels	PROVED — mathematical argument in Chapter 4, five specific deficiencies demonstrated
The 15 features are stationary and OTC-compliant	PROVED — by construction (all formulas use only {Bid, Ask, Flags, Tick_Time_ms})
The algo-phase detection paradigm is theoretically superior	ARGUED — supported by microstructure theory but not yet empirically validated on live data
Titan V3.0 produces alpha in live EURUSD trading	NOT YET PROVED — empirical results chapter (Ch 13) pending live/backtest data
Novel features (QAD, SGC, TDA, MFE) outperform standard features	NOT YET PROVED — baseline comparison (Ch 12) pending empirical results

15.3 Future Research Directions

Direction	Expected Impact
True C++ ripser DLL for MQL5 TDA features	Eliminates H0/H1 approximation, achieves full Python-MQL5 parity on all 15 features

Transformer encoder replacing LSTM	Self-attention may capture non-local phase cycle dependencies across the 128-tick window more efficiently than recurrent state
Reinforcement learning (POMDP formulation)	Eliminates binary labeling entirely; RL agent maximises Sharpe directly from microstructure observations
Multi-broker ensemble	Combines phase signals from 3+ brokers; reduces single-LP microstructure dependency
Level 2 DOM depth integration	True bid/ask depth imbalance features from the full order book are the richest possible signal source
Cross-asset phase correlation	EURUSD → GBPUSD → USDJPY phase signals: same institutional participants, potentially correlated cycles

Final Statement

The edge in high-frequency OTC Forex trading does not live in price patterns. Price is the exhaust of a causal chain that began 50 to 500 milliseconds earlier in an institutional portfolio manager's decision, mediated by a Smart Order Router, and executed by a deterministic algorithm with observable behavioral signatures. Titan V3.0 reads those signatures. It exploits obligations, not coincidences. Obligations persist. Coincidences decay. That is the foundational asymmetry on which this system is built.
